Abstract

The electrical resistivity of YbAgCu₄ has been measured at pressures up to 100 kbar and at temperatures between 1 and 300 K. With increasing pressure, the resistivity maximum shifts to lower temperatures and the coherent regime disappears above about 60 kbar. At the highest pressures, a field of 8 T produces a large negative magnetoresistance, roughly equivalent to a negative pressure of 30 kbar. The behavior is consistent with a pressure-induced decrease in the Kondo temperature.

The compound YbAgCu₄ has a cubic-crystal structure and is one of the few Yb-based heavy-fermion compounds with a large linear coefficient of specific heat $\gamma = 245$ mJ/mol K² [1]. At ambient pressure, this compound shows no phase transition down to 80 mK and has a relatively large $T^2$-coefficient of resistivity ($A = 0.06 \, \mu\Omega \cdot \text{cm} / \text{K}^2$) that persists up to 15 K [2]. Unlike Ce- and U-based heavy-fermion compounds in which pressure $P$ depresses the heavy-mass state, as evidenced by decreases in $\gamma$ and $A$, pressure enhances $A$ in YbAgCu₄ for $P \leq 18.3$ kbar. This behavior has been interpreted as due to a decrease in the Kondo temperature ($T_K$) with increasing $P$ and suggests that for sufficiently high $P$ the Kondo scale would eventually become smaller than the RKKY scale and YbAgCu₄ should order magnetically at some elevated pressure [2]. Evidence for this trend has been reported for YbCuAl which has a $\gamma$ at $P = 0$ comparable to that of YbAgCu₄ and which appears to order magnetically for $P \geq 100$ kbar [3]. With the objective of observing magnetic ordering in YbAgCu₄, we have measured the resistivity $\rho(T)$ between 1.2 and 300 K and at $P \leq 100$ kbar.

The sample was prepared by melting a mixture of stoichiometric amounts of Yb, Ag, and Cu which were sealed in a tantalum tube. The melt was slowly cooled to room temperature, allowing the growth of polycrystalline YbAgCu₄. Electrical resistivity measurements were carried out using a standard four-probe configuration and a LR-400 AC resistance bridge. The pressure was generated in a Bridgman-type cell with steatite as the pressure transmitting medium and lead as a pressure manometer.

The electrical resistivity $\rho$ as a function of $T$ is plotted at various pressures in Fig. 1. Inspection of the low-temperature behavior in the inset shows that the $T^2$-coefficient and the residual resistivity $\rho(1.2 \, \text{K})$ increase with pressure while the temperature range over which $\rho \propto T^2$ is reduced with increasing pressure. For $P > 60$ kbar there is no evidence for a coherent regime ($\rho \propto T^2$) above 1.2 K. These observations are consistent with a strongly

Fig. 1. Electrical resistivity $\rho$ versus temperature $T$ of YbAgCu$_4$ at various pressures between 14 and 98 kbar. Inset: $[\rho - \rho(1.2 \text{ K})]$ as a function of $T^2$ at the same pressures.

Fig. 2. Electrical resistivity $\rho$ versus temperature $T$ of YbAgCu$_4$ at 73 kbar in 0 and 8 T. Data points for intermediate fields of 4 T (circles) and 6 T (stars) are also shown. The broken lines are guides to the eye. Inset: Normalized magnetoresistance $\rho(H)/\rho(H = 0)$ as a function of the magnetic field $H$ at 98 kbar and temperatures of 1.3 K (bottom curve), 4, 15, 33 and 41 K (upper curves).

volume-dependent reduction of the conduction electron–Yb localized 4f electron antiferromagnetic coupling constant $J$ and are in agreement with Doniach's phase diagram [4]. Therefore, from the expression $T_K \propto \exp(-1/N(E_F))$, where $N(E_F)$ is the density-of-states at the Fermi energy, we expect a smaller Kondo temperature at higher pressures. The evolution of $\rho(1.2 \text{ K})$ and $A$ then suggests that both are proportional to $T_K^c$, with the exponent $c$ of the order of 0.5 and 2–2.5, respectively, as argued by Flouquet et al. and Barbara et al. [5, 6]; i.e., for YbAgCu$_4$ the low-$T$ transport is increasingly dominated by Kondo spin fluctuations at high pressure. If this is so, we would expect $\rho(\text{low}-T)$ to diminish with applied field since a magnetic field should suppress the spin fluctuations. Figure 2 shows that this is the case. For $P = 73$ kbar and high fields, we see that a $\rho \propto T^2$ behavior is recovered and $\rho(1.2 \text{ K})$ and the $T^2$-coefficient decrease with increasing $H$. Comparing the resistivity curves of $P = 73$ kbar and $H = 8$ T with $P = 56$ kbar and $H = 0$ suggests that an 8 T field is roughly equivalent to a negative pressure of 15 kbar. At 98 kbar a magnetic field of 8 T modifies the resistivity curve even more significantly and corresponds to a negative pressure of more than 30 kbar. To our knowledge, this is the first example where $P$ and $H$ exhibit opposite (but consistent) effects on the low-temperature resistivity of a heavy-fermion compound. These results support strongly that $\rho(\text{low}-T)$ is dominated by Kondo-spin fluctuations. The inset of Fig. 2 shows the large negative magnetoresistance above and below $T_K$ which confirms the important role of Kondo spin fluctuations in the scattering process at low temperature. No magnetic phase transition has been found above 1.2 K and pressures as high as 98 kbar (Fig. 1).
