We report photomodulation spectroscopy measurements of the pressure dependence of the optical transition in Zn$_{1-y}$Mn$_y$O$_x$Te$_{1-x}$ alloys that is associated with the lowest Γ conduction band (termed $E_\_ \_ subband). The pressure-induced energy shift of the $E_\_ \_ transition is nonlinear and much weaker as compared to change of the direct band gap of Zn$_{0.88}$Mn$_{0.12}$Te. The weak pressure dependence of the $E_\_ \_ transition can be fully understood based on the band anticrossing model in which the $E_\_ \_ subband results from an interaction between the extended ZnMnTe conduction-band states and the localized O electronic states.

PACS numbers: 71.20.-b, 71.20.Nr, 72.80.Ey, 78.20.-e
The discovery of band anticrossing induced conduction band splitting caused by the strong interaction between the extended conduction band states and localized N resonant states in Ga$_{1-x}$In$_x$N$_y$As$_{1-y}$ alloys$^1$ has led to extensive studies on the properties of so-called highly mismatched alloys (HMAs) in which a small fraction of the constituent anion element is replaced by an element with highly dissimilar properties in terms of electronegativity and atomic size.$^{2-10}$ The dramatic changes of the electronic properties caused by substitution of the group V element in group III-V compounds with small amounts of nitrogen at alloy-like concentrations, such as a pronounced reduction of the fundamental band-gap energy,$^{11,12}$ a significant increase in electron effective mass and a decrease in electron mobility,$^{7,13,14}$ as well as the appearance of a new optical transition ($E_v$) from the valence band to the conduction band at the $\Gamma$ point,$^{1,4,15}$ have been well explained by the band anticrossing (BAC) model.$^{1,2}$

The anticrossing interaction between the extended conduction-band states of a semiconductor matrix and the highly localized electronic states introduced by the isoelectronic substitutional atoms with high electronegativity, such as N in GaAs or O in ZnSe, can be expressed as$^{1,2}$

$$E_{\pm}(k) = \frac{1}{2} \left\{ (E_M(k) + E_D) \pm \sqrt{(E_M(k) - E_D)^2 + 4V^2} \right\}, \quad (1)$$

where $E_M(k)$ and $E_D$ are the energies of the unperturbed conduction band and of the localized states relative to the top of the valence band, respectively. The matrix element describing the interaction and hybridization between the localized states and the extended conduction-band states $V=C_{MD}x^{1/2}$, where $C_{MD}$ is a constant dependent on the semiconductor matrix and $x$ is the alloy composition. The energy positions of the subband edges given by Eq.(1) depend on the interaction parameter $V$ and the location of $E_D$ with respect to the conduction band edge $E_M$.

Illustrated in Fig. 1 are schematic examples of the calculated band structure based on the BAC
model. The interaction between the localized isoelectronic states and the extended conduction-band states has a pronounced effect on the dispersion relation of the two conduction subbands $E_-$ and $E_+$. If the localized state is located within the conduction band of the matrix, as depicted in Fig.1(a), the conduction-band states at the $E_-$ edge retain mostly the extended $E_M$-like character and those at the $E_+$ edge are more of localized and $E_D$-like character. If the localized states lie below the conduction-band edge, as displayed in Fig.1(b), the conduction-subband edges $E_-$ and $E_+$ switch their characters: the $E_-$ subband states have the highly localized nature and $E_+$ subband states possess the character of extended state.

To date, most experimental studies have concentrated on the case of the localized state resonant with the conduction band, such as the well known case of GaN$_x$As$_{1-x}$. In this work, we address the case in which the localized state is located below the conduction band and within the forbidden gap of a semiconductor matrix. Specifically, we study the effect of applied pressure on the band structure of Zn$_{1-y}$Mn$_y$O$_x$Te$_{1-x}$ alloys. We show that the formation of $E_-$ and $E_+$ bands in Zn$_{1-y}$Mn$_y$O$_x$Te$_{1-x}$ can be demonstrated experimentally and the characteristic signature of the $E_-$ subband edge can be verified unmistakably by its pressure dependence.

The Zn$_{1-y}$Mn$_y$O$_x$Te$_{1-x}$ samples used in this work are synthesized using O ion implantation followed by pulsed laser melting (PLM). This approach is very effective in incorporating impurities into a crystal to levels well above the solubility limit due to the rapid recrystallization rate. Synthesis of diluted GaN$_x$As$_{1-x}$, as well as ferromagnetic Ga$_{1-x}$Mn$_x$As using the PLM process has recently been demonstrated. Multiple energy implantation using 30 and 90 keV O$^+$ ions was carried out into Zn$_{0.88}$Mn$_{0.12}$Te single crystals to form ~0.2 µm thick layers with relatively constant O concentrations corresponding to O mole fractions of 0.0165-0.044. The reason of using ternary ZnMnTe as substrates is that the presence of Mn enhances and stabilizes
the incorporation of O. The O⁺-implanted samples were pulsed-laser melted in air using a KrF laser ($\lambda = 248$ nm) with a pulse duration ~38ns. After passing through a multi-prism homogenizer, the fluence at the sample ranged between 0.020 and 0.3 J/cm².

Photomodulation spectroscopy measurements were carried out to measure the energies of the optical transitions in the samples in both transmission (PT) and reflection (PR) configurations. Quasimonochromatic light from a Xenon arc lamp dispersed by a 0.5-m monochromator was focused on the samples as a probe beam. A chopped HeCd laser beam (3250 or 4420 Å) provided the photomodulation. The photomodulated spectral signals were detected by a Si photodiode using a phase-sensitive lock-in amplification system. Application of hydrostatic pressure was accomplished by mounting small sample chips with sizes of ~200×200 µm² into a gasketed diamond anvil cell.

Figure 2 shows PR spectra taken at 80 K from two Zn$_{0.88}$Mn$_{0.12}$O$_x$Te$_{1-x}$ samples implanted with 3.3% O⁺ followed by PLM with laser energy fluence of 0.15 and 0.3 J/cm², as well as from the Zn$_{0.88}$Mn$_{0.12}$Te used as the substrate in this work. The actual “active” O concentration (x) in the Zn$_{0.88}$Mn$_{0.12}$O$_x$Te$_{1-x}$ samples is estimated to be roughly around 1%. However, its precise value is not very important in the discussion presented here. The derivative-like spectral feature in the PR spectrum of Zn$_{0.88}$Mn$_{0.12}$Te corresponds to the optical transition from the valence-band edge to the conduction-band edge. The band-gap energy is found to be 2.40 eV at 80 K for the Zn$_{0.88}$Mn$_{0.12}$Te matrix. For the oxygen containing samples, the PR spectra exhibit two features with energies distinctly different from the fundamental band gap of Zn$_{0.88}$Mn$_{0.12}$Te matrix. These two transitions are assigned to those from the top of the valence band to the two conduction subband edges, $E_-$ (~1.85 eV) and $E_+$ (~2.6 eV), formed by the band anticrossing interaction between the localized O states and the extended conduction-band states.
of ZnMnTe matrix as illustrated by Fig. 1(b). The strong photomodulation signals of both $E_-$ and $E_+$ indicate the band-to-band nature of these transitions and suggest that the $E_-$ transition has substantial oscillator strength comparable to that of the $E_+$ transition.

To further elucidate the origin of the $E_-$ band we have studied the effects of hydrostatic pressure on the $E_-$ transition. The energy positions of the $E_-$ transition in the sample treated by PLM with a laser energy fluence of 0.3 J/cm$^2$ has been measured as a function of applied hydrostatic pressure at room temperature. The results are shown in Fig. 3, along with the measured pressure dependence of the band gap of the Zn$_{0.88}$Mn$_{0.12}$Te matrix. The room-temperature energy position of the $E_+$ transition at atmospheric pressure is also shown in the figure. The inset shows a typical PT spectrum recorded at high pressures. By fitting the experimental data (open circles in Fig.3) to $\Delta E(P) = \alpha P$ with $\alpha = dE_g/dP$, the pressure dependence of the Zn$_{0.88}$Mn$_{0.12}$Te band gap is found to be $dE_g/dP = 8.5$ meV/kbar. It is not surprising to see that the pressure-induced energy shift of the $E_-$ transition is much weaker (initial slope $\approx 2$ meV/kbar) and nonlinear as compared to change of the direct band gap of Zn$_{0.88}$Mn$_{0.12}$Te. The weak pressure dependence of the $E_-$ transition can be fully understood with the BAC model. The fact that $E_-$ is located much closer to the energy level of the localized O states [Fig.1(b)] gives its wavefunction a pronounced O-like character. The solid lines through the experimental data in Fig. 3 are the calculated pressure dependencies of $E_-$ and $E_+$ transitions using Eq. (1). The best fits to the data yield the energy position of O level (relative to the top of the valence band) $E_O = E_V + 2.0 \pm 0.1$ eV at atmospheric pressure with a pressure dependence of $0.6 \pm 0.1$ meV/kbar. It is clear from the figure that the pressure dependence of the $E_-$ transition is slightly stronger than that of the O level as expected from the admixture of extended conduction-band $\Gamma_C$ states of matrix to the $E_-$ band-edge states. On the other hand, the much weaker pressure dependence of
the $E_-$ transition as compared to that of the conduction-band $\Gamma_C$ edge indicated the predominantly O-like nature of the $E_-$ band.

The present results have important inferences for the understanding of the origin of the unusual electronic structure of HMAss. They show that the electronic structure of different HMAss can be explained by the BAC model with a common picture. They also provide strong arguments against other previously proposed models. It has been argued that the electronic structure of GaN$_x$As$_{1-x}$ alloys results from an interaction between the closely lying $\Gamma_C$, $L_C$, and $X_C$ minima.$^{21-23}$ The interaction is caused by the perturbation potential resultant from the substitution of N atom to As atom. In these models the smaller and pressure-dependent pressure coefficient of the $E_-$ transition observed in GaN$_x$As$_{1-x}$ alloys was attributed to the increasing contribution of the $L_C$ and $X_C$ minima whose pressure coefficients are much smaller than that of the $\Gamma_C$ minimum. Apparently, these models cannot explain the results presented here. The large downward shift of 0.5 eV of the conduction band minimum ($E_-$) and the very weak pressure dependence of the band energy as shown in Fig.3 cannot be attributed to the influence from the conduction-band $L$ and $X$ edges because they are located far away from the $\Gamma_C$ edge (>1.0 eV) in Zn$_{1-y}$Mn$_y$Te.$^{24}$ Thus, our results directly confirm that the $E_-$ transition together with the $E_+$ are the results of a band anticrossing interaction between the extended $\Gamma$ conduction-band states and highly localized states in highly mismatched alloys.

In conclusion, we have studied the effect of pressure on the electronic band structure of Zn$_{1-y}$Mn$_y$O$_x$Te$_{1-x}$ alloys by investigating the optical transitions associated with the $\Gamma$ point at the conduction-band and the valence-band edges. The Zn$_{1-y}$Mn$_y$O$_x$Te$_{1-x}$ samples were found to exhibit a classical band-anticrossing behavior with the formation of two conduction subbands ($E_-$ and $E_+$) resulting from the strong interaction between the extended conduction-band states of
Zn$_{1-y}$Mn$_y$Te and the localized O states. By examining the effect of applied pressure on the $E_\text{\textunderscore} E_n$ transition, we are able to derive the energetic position of $E_0=E_V+2.0\pm0.1$ eV for the localized O level and its pressure dependence of $0.6\pm0.1$ meV/kbar from the experimental results.
